

Pressure Drop for Gas and Non-Newtonian Liquid Two-Phase Flows across Sudden Expansion in Horizontal Rectangular Mini-Channel

Daiki Goto*, Agus Santoso, Tomoaki Takehira, Ahmad Aslam, Akimaro Kawahara, Michio Sadatomi

Graduate School of Science and Technology, Kumamoto University, Japan

Abstract Experimental investigations were conducted for gas-liquid two-phase flow through sudden expansion in horizontal rectangular mini-channel. The cross-sectional dimensions of the channel with the height (H), the width (W) and the hydraulic diameter (D_H) for the narrow channel are 2.79 mm, 3.09 mm and 2.94 mm, while those for the wide channel are 2.95 mm, 5.98 mm and 3.95 mm. In order to know the effects of liquid properties, water and viscoelastic liquid, namely 0.4 wt % polyacrylamide (PAM) aqueous solution are selected as the working liquids, while air as the working gas. The local pressures upstream and downstream from the expansion were measured with calibrated pressure sensors, and the pressure distribution map was drawn to determine the frictional pressure drop in the test channel and the pressure change at the expansion for single-phase and two phase flows. The pressure change data at the expansion for two-phase flows were compared with the calculations by several correlations in some literatures. These are reported in the present paper.

Keywords Rectangular mini-channel, Two-phase flow, Sudden expansion, Non-Newtonian fluid

1. Background

The flow channel normally involves several geometrical singularities such as abrupt area changes (sudden expansion, sudden contraction, valve or orifice). The flow of two-phase mixtures across sudden expansions and contractions is commonly seen among piping connections as well as relevant to many applications such as chemical reactors, power generation units, oil wells and petrochemical plants (Wang et al., 2010). In particular, the small and narrow channels are widely adopted in compact heat exchangers (Chen et al., 2009). One of the simplest arrangements for the heat removal is using the liquid flow and convective heat transfer with or without phase change in small rectangular channels (Chen et al., 2007). Recently, such a flow through singularity in micro and mini-channels of 100 μm to 10 mm becomes popular because compact heat exchangers with phase change, such as cooling devices of electronic equipment and refrigerators, are miniaturized (Sadatomi et al., 2013). Therefore, the understanding of the characteristics on two phase flow through the singularities in mini-channel is essential for designing and developing such small scale devices.

Regarding gas-liquid two-phase flows through a sudden

expansion in mini-channels, several studies have been reported. Abdelall et al. (2005) performed an experimental study of pressure drop caused by abrupt flow area changes in small circular channels. The larger and smaller tube diameters were 1.6 and 0.84 mm, respectively. Deionized water and air were used as two-phase working fluids. Chen et al. (2008) conducted experimental investigation of the two-phase flow characteristics across sudden expansion using air and water. The expansion test section was from small rectangular channels (3 by 6 mm and 3 by 9 mm in short and long sides) into a small circular tube (3 mm in diameter). Sadatomi et al. (2013) investigated air-water two-phase flow through a sudden expansion in a horizontal rectangular mini-channel with 3.03 mm by 3.02 mm and 5.97 mm by 3.09 mm in the width and the height. The two-phase pressure drop at the expansion was the best predicted by Wadle's correlation (1989).

From the above discussion, it is cleared that most studies have been conducted based on the Newtonian fluid data as the test liquid, and there are a few data using non-Newtonian liquids, seen in chemical reactor and bio reactor etc. (Böhm et al., 2014). In this connection, the aim of this study is to investigate experimentally the effects of non-Newtonian liquid on the pressure change at a sudden expansion. Adiabatic experiments were conducted to obtain such data for gas-liquid two phase flows through a sudden expansion in a horizontal rectangular mini-channel. The cross-sectional sizes of the channel were 3.09mm by 2.79 mm and 5.98 mm by 2.95 mm. The corresponding area ratio was $\sigma_A = 0.49$. In

order to study the effects of non-Newtonian properties, water and aqueous solution of polyacrylamide (PAM), which exhibits pseudo plastic with viscoelasticity, were used as the test liquid, while air as the test gas. The present pressure change data obtained from air-water and air-PAM system are compared with calculation by correlations in literatures. Results of the experiments and the comparison are described in this paper.

2. Experimental Methods

2.1. Test Apparatus

Figure 1 shows a schematic diagram of the test channel with a sudden expansion placed on a horizontal plane. The test channel is rectangular in cross-section and is made of transparent acrylic resin for visual observation. Table 1 shows the cross-sectional dimensions of test channel with the width (W), the height (H) and the hydraulic diameter (D_H): They are 3.09 mm, 2.79 mm and 2.94 mm for the narrow channel, while 5.98 mm, 2.95 mm and 3.95 mm for the wide channel, thus the area ratio σ_A is about 0.49.

The ports #1 and #2 in Fig. 1 were the liquid and the gas inlet ports. Therefore, two phases were supplied through a T-junction type gas-liquid mixer. The port #6 was the outlet of the gas-liquid mixture to atmosphere. The ports #3, #4 and #5 were closed in the present experiment. It is noted that if ports #5 and #6 were used as the inlet ports of gas and liquid, and ports #4, #2 and #3 were closed, the sudden contraction test can be conducted with the same test channel.

Table 1. Dimensions of test channel cross section

	W [mm]	H [mm]	D_H [mm]
Narrow, N	3.09	2.79	2.94
Wide, W	5.98	2.95	3.95

P_1 to P_{12} are the pressure taps, and the pressure at P_4 was measured with a gauge type pressure transducer (Yokogawa, FP101-L31-L20). The pressures at other pressure taps were determined from the difference in pressure between the respective taps and P_4 tap measured with a differential

pressure transducer (Validyne, DP15-32 and DP15-26 depending on the pressure range). The accuracy of the pressure measurement was confirmed within 3.5 Pa from a calibration test. Volume flow rate of air was measured with a flow meter (KEYENCE, FD-A10 and FD-A1 depending on the flow rate range) with accuracy of 3%, while that of liquids with a flow meter (KEYENCE, FD-S) with accuracy of 2%. In order to obtain accurate time averaged values of air and water flow rates and pressures, the output signals from the respective sensors were fed to a personal computer via A/D converter at nominally 2 kHz over 20 sec.

In this study, tap water and aqueous solution of 0.4 wt % polyacrylamide (PAM) are selected as the test liquid, while air at room temperature as the test gas. PAM aqueous solution is known as a kind of non-Newtonian fluid having viscoelasticity (Chhabra *et al.*, 1984). Also, PAM aqueous solution has shear thinning effect where the fluid's viscosity decreases with increasing of shear rate and is often expressed by the Ostwald-de Waele power law model as follows:

$$\tau = K \left(\frac{du}{dy} \right)^n = K \left(\frac{du}{dy} \right)^{n-1} \frac{du}{dy} = \mu_a \frac{du}{dy} \quad (1)$$

where τ is the shear stress, du/dy the shear rate, K the consistency coefficient, n the flow index and $\mu_a (= K(du/dy)^{n-1})$ the apparent viscosity. In this study, the values of K and n for each test liquids were determined with a capillary method (Farooqi *et al.*, 1980), and are listed in Table 2 together with the density and the surface tension. n for both water and PAM aqueous solution are investigated within the share rate range of 80 to 12000 1/s. In addition, the density and the surface tension are nearly the same between water and PAM aqueous solution. So, any changes in the test results are due mainly to the change in the viscosity of the test liquid.

Table 2. Physical properties of test liquids

Working liquids	K [Pa·s ^{n}]	n	ρ [kg/m ³]	σ [N/m]
Water	0.00095	1.00	998	0.073
PAM 0.4wt%	0.0136	0.85	999	0.072

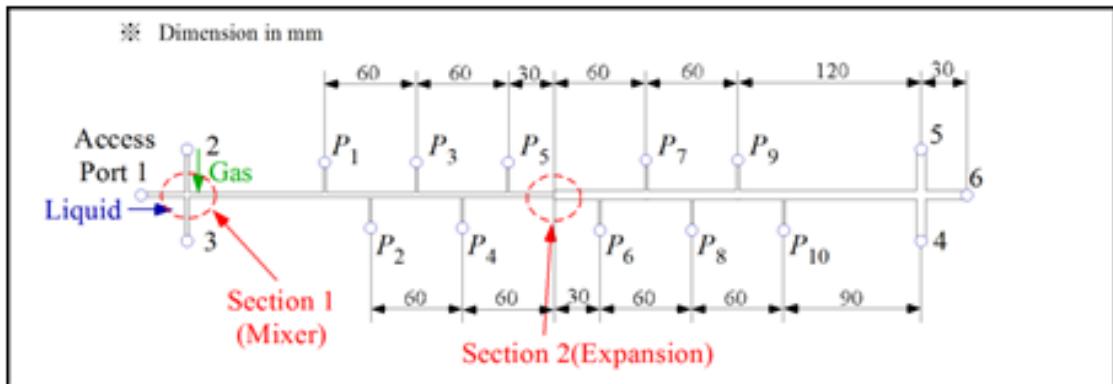

Figure 1. Test channel with sudden expansion

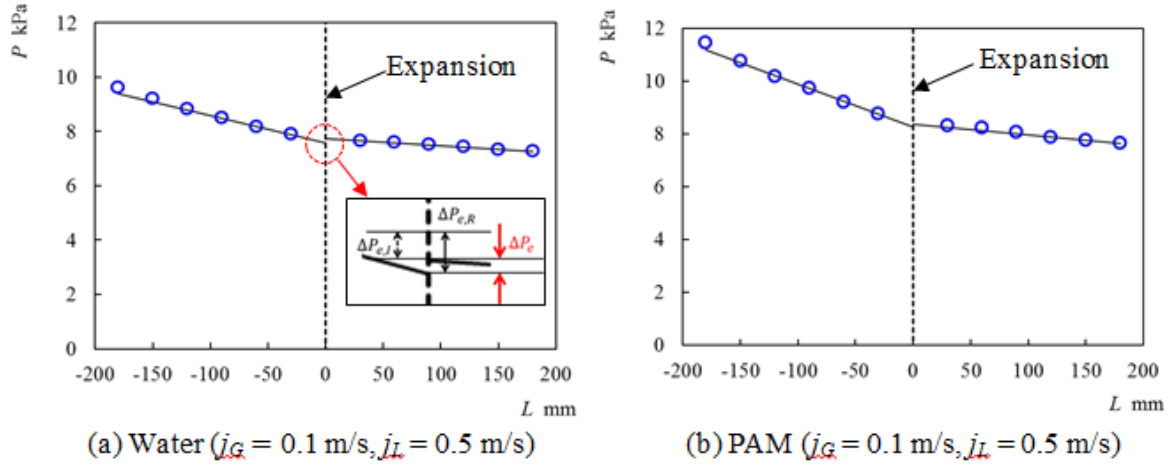

Figure 2. Pressure distribution along upstream and downstream from expansion

For single-phase flow experiments, the ranges of the mean velocity u were changed from 0.1 to 2 m/s in the narrow channel for both test liquids. For two-phase flow experiments, the volumetric fluxes of liquid and gas were changed as $j_L = 0.5, 1$ m/s and $j_G = 0.1, 0.5, 1, 5, 10$ m/s for both test liquids. The fluid temperature was 20 to 25°C.

2.2. Data Reduction for Pressure Change at Expansion

Figures 4 (a) and (b) show examples of the pressure distribution data obtained for air-water and air-PAM aqueous solution two-phase flows at $j_G = 0.1$ m/s and $j_L = 0.5$ m/s. The ordinate is the gauge pressure, while the abscissa is the distance from the expansion. The total pressure change across sudden expansion, ΔP_e , was determined by the extrapolations of the axial pressure profiles upstream and downstream from the expansion. ΔP_e consists of the reversible pressure rise, $\Delta P_{e,R}$, and irreversible pressure drop, $\Delta P_{e,I}$ as shown by pattern diagram in Fig. 2 (a).

3. Results and Discussions

3.1. Single-phase Friction Factor

In order to check the accuracy of the pressure measurement, the single-phase friction factors were determined from the fully developed upstream and the downstream pressure gradients. Figs. 3 (a) and (b) show the Darcy friction factor data respectively for the channels upstream and downstream of the expansion. The data of water are plotted against the Reynolds number ($= \frac{\rho u D_H}{\mu}$, where μ is the viscosity, u is the mean velocity). On the other hand, in the case of PAM aqueous solution, the generalized Reynolds number (Kozicki et al., 1966) was used to consider non-Newtonian properties, and this is given by:

$$Re^* = \frac{8^{1-n} \rho D_H^n u^{2-n}}{K} \left(\frac{n}{a + bn} \right)^2. \quad (2)$$

Here, a and b are constants depending on the cross-sectional shape of the channel. In the present case, $a = 0.213$ and $b =$

0.677 for the narrow channel, while $a = 0.242$ and $b = 0.725$ for the wide channel. The present data in laminar flow region are compared with calculated curve by Shah and London (1978) which is a function of aspect ratio, $\alpha^* (= W/H)$, for a rectangular channel:

$$\lambda Re(Re^*) = 96(1 - 1.355\alpha^* + 1.947\alpha^{*2} - 1.701\alpha^{*3} + 0.9564\alpha^{*4} - 0.2537\alpha^{*5}) \quad (3)$$

In addition, the data in turbulent flow are compared with calculated line by Sadatomi et al. (1982). As seen in Fig. 3, most data for water approached to such calculated lines. In the case of PAM, the data in laminar flow also approached to the lines by use of the generalized Reynolds number, however, in present experimental condition, the data in turbulent flow were not observed because of high viscosity of PAM.

3.2. Single-phase Pressure Change at Expansion

The data of single-phase pressure change at expansion, ΔP_e , are plotted in Fig. 4. ΔP_e for both the water flow and the PAM flow increase with the mean velocity of liquid in narrow channel, u_N . This is caused by the increase in the ratio of reversible pressure rise, $\Delta P_{e,R}$, against irreversible pressure drop, $\Delta P_{e,I}$. In the case of PAM, for PAM ΔP_e were higher than that of water. From this results, it is found that $\Delta P_{e,I}$ for PAM is smaller than water.

3.3. Expansion Pressure Loss for Single-phase Flow

By substituting ΔP_e data into the following equations, we determined the experimental value of an expansion pressure loss coefficient for single-phase liquid flow, k_e :

$$k_e = \frac{\Delta P_{e,R} - \Delta P_e}{\frac{\rho u_N^2}{2}}. \quad (4)$$

Here,

$$\Delta P_{e,R} = \frac{\rho u_N^2}{2} (1 - \sigma_A^2). \quad (5)$$

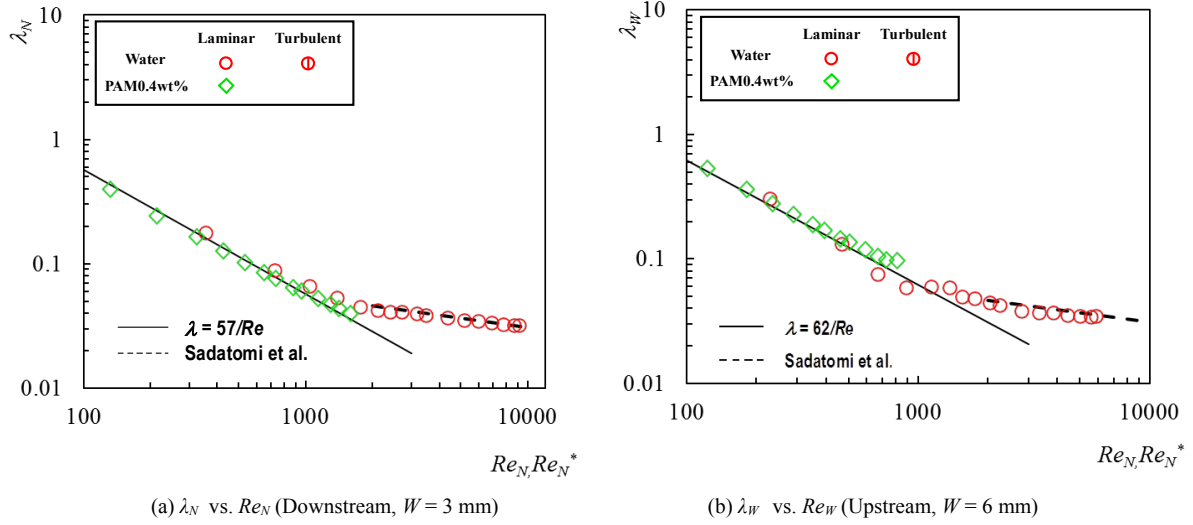

Figure 3. Single-phase friction factors in channels upstream and downstream from the expansion

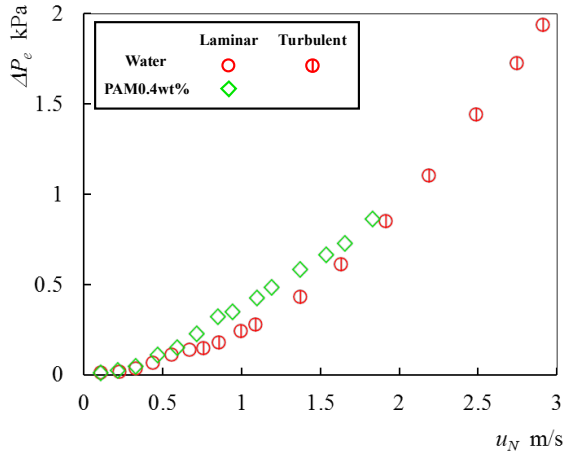

Figure 4. Single-phase pressure change at expansion

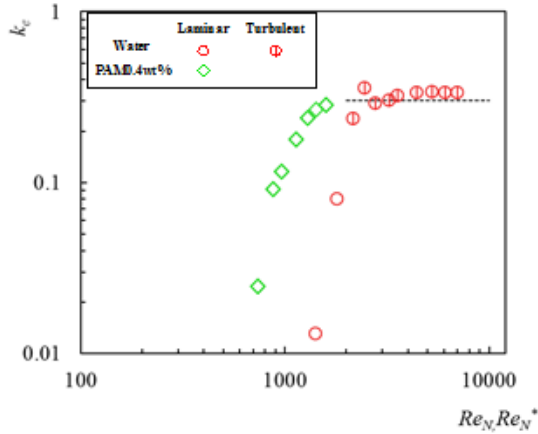

Figure 5. Expansion loss for single phase flow

The resulting k_e values are plotted in Fig. 5. In addition, broken line shows the calculation by Borda-Carnot's formula ($= (1 - \sigma_A^2)$). As seen in this figure, the k_e data gradually approach the calculation line with the increase in Re_N or Re_N^* , and the water data in turbulent flow become almost constant and nearby the calculation line. The PAM data also approach the calculation line though no data was obtained in turbulent flow region.

3.4. Flow Pattern

Figure 6 shows typical upside view of flows downstream of the expansion for air-water and air-PAM flow in the wide channel. Three types of flow pattern, (a) a bubbly flow, (b) a slug flow and (c) an annular flow, were observed for both air-water and air-PAM flows under the present flow conditions. In the bubbly flow, bubble size is smaller for air-PAM flow than air-water flow. In addition, the bubbles tend to drift to right or left side wall of the wide channel. This drift is not due to the gravity effect because the gravity direction is perpendicular to the paper. For the slug flows of both air-water and air-PAM flows, the bubble length becomes longer than that for the bubbly flow. The bubble length is longer for air-PAM flow than air-water one, and the bubble nose become sharper for air-PAM flow. Furthermore, liquid film thickness around the gas bubble is thicker for air-PAM flow than air-water flow. For the annular flow, the liquid flow as liquid film on the channel wall, and gas flow in core of the channel. The liquid film thickness is thicker for air-PAM flow than air-water flow. The thicker liquid film for the slug and annular flows might be caused by higher viscosity of PAM solution.

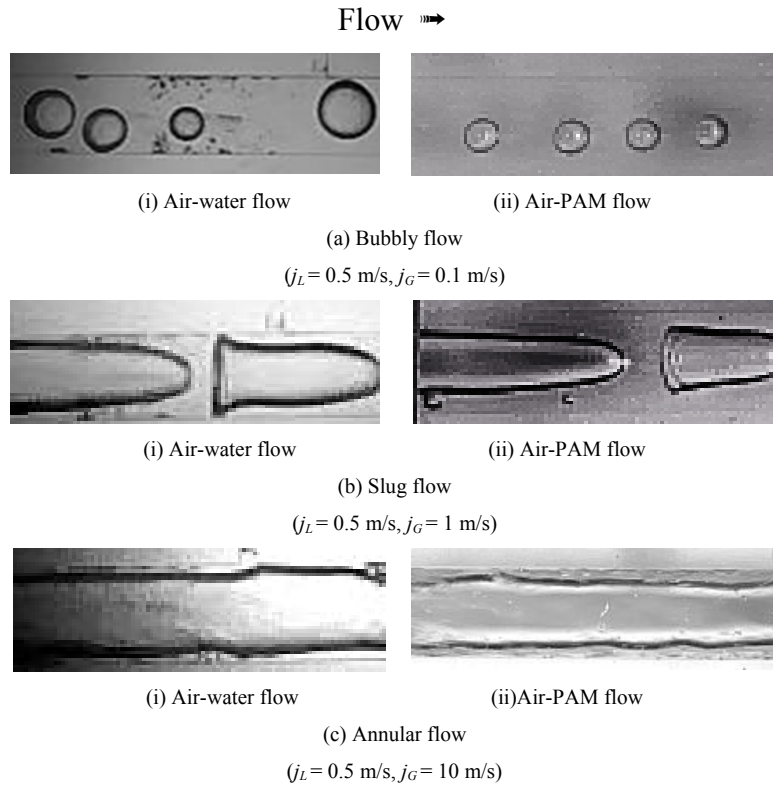

Figure 6. Typical flow in the test channel

3.5. Two-phase Pressure Change at Expansion

The data on the two-phase pressure change at expansion, ΔP_e , are plotted against the gas volumetric flux, j_G in Fig. 7. The data points are marked with different symbols depending on the test liquid and the liquid volumetric flux, j_L . In the case of water, at both $j_L = 0.5$ and 1 m/s, ΔP_e increased with increasing of j_G . This indicates that the effect of the expansion on reversible pressure rise becomes profound due to the increase in mean liquid velocity caused by the increase in void fraction. ΔP_e were higher for PAM than water when j_G is low. This result means that the ratio of irreversible pressure drop to reversible pressure rise for PAM become smaller than that for water, that is, the effect of the expansion on flow disturbance is significant at low j_G .

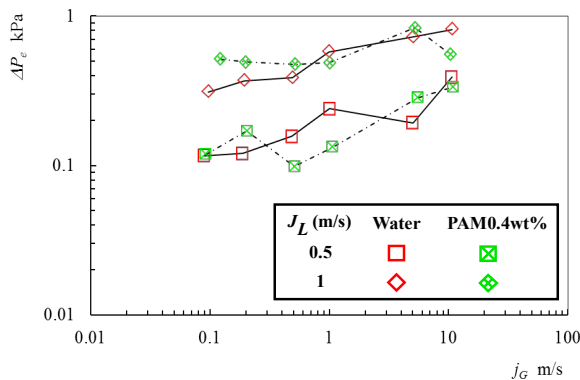

Figure 7. Two-phase flow pressure change at expansion

3.6. Validation Test of Correlation for Two-phase ΔP_e

In order to find better correlation for predicting two-phase pressure change at expansion, the present ΔP_e data was compared with five prediction model/correlations proposed for gas and Newtonian liquid two-phase flow. Table 3 lists the root mean square values of absolute error, $\Delta P_{e,cal} - \Delta P_{e,exp}$, respectively for the air-water flows, the air-PAM flows and all the flows.

Table 3. RMS errors in ΔP_e prediction

Correlations	$\varepsilon_{ABS,M}$ kPa Water	$\varepsilon_{ABS,M}$ kPa PAM	$\varepsilon_{ABS,M}$ kPa ALL
Shmidt and Friedel (1996)	0.102	0.172	0.200
Wadle (1989)	0.200	0.179	0.268
Abdellal et al. (2005)	0.147	0.164	0.220
Collier and Thom (1994)	0.175	0.160	0.240
Slip flow model proposed by Abdelal et al. (2005)	0.331	0.356	0.485

Figures 8 (a) - (e) compare the two-phase pressure change between experiment and calculations. Four correlations except for a slip flow model proposed by Abdelal et al. (2005) predict well the present data, although the correlations by Wadle (1989), Abdelal et al. (2005) and Collier and Thom (1994) tend to under-predict the data. Among these correlations, the following Shmidt and Friedel's correlation gave the best prediction.

$$P_{et} = - \frac{G_N^2 \left[\frac{\sigma_A}{\rho_{eff}} - \frac{\sigma_A^2}{\rho_{eff}} - f_e \rho_{eff} \left(\frac{x}{\rho_G \alpha} - \frac{1-x}{\rho_L (1-\alpha)} \right) (1 - \sqrt{\sigma_A})^2 \right]}{1 - \Gamma_e (1 - \sigma_A)}, \quad (6)$$

where,

$$\frac{1}{\rho_{eff}} = \frac{x^2}{\rho_G \alpha} + \frac{(1-x)^2}{\rho_L (1-\alpha)} + \frac{\alpha_E \rho_L (1-\alpha)}{1-\alpha_E} \left[\frac{x}{\rho_G \alpha} - \frac{1-x}{\rho_L (1-\alpha)} \right]^2 \quad (7)$$

$$\alpha = 1 - \frac{1(1-x)^2}{1 - 2x + \sqrt{1 + 4x(1-x) \left(\frac{\rho_L}{\rho_G} - 1 \right)}} \quad (8)$$

$$\alpha_E = \frac{1}{S} \left[1 - \frac{1-x}{1-x(1-0.05We^{0.27} Re^{0.05})} \right] \quad (9)$$

$$S = \frac{x}{1-x} \frac{(1-\alpha)}{\alpha} \frac{\rho_L}{\rho_G} \quad (10)$$

$$We = G_N^2 x^2 \frac{D_H}{\rho G^\sigma} \frac{\rho_L - \rho_G}{\rho_G} \quad (11)$$

$$Re = \frac{G_N (1-x) D_H}{\mu_L} \quad (12)$$

$$\Gamma_e = 1 - \sigma_A^{0.25} \quad (13)$$

$$f_e = 4.9 \times 10^{-3} x^2 (1-x)^2 \left(\frac{\mu_L}{\mu_G} \right)^{0.7} \quad (14)$$

In these equations, the subscripts L , G means liquid and gas, respectively. x is the quality, G_N the total mass flux in narrow channel, ρ_{eff} the effective density in two-phase mixture, α the void fraction. In addition, α_E the mean volumetric entrainment, S are the slip ratio, We the Weber number, and Γ_e the base pressure coefficient, f_e the friction factor in expansion.

In the present calculation, non-Newtonian properties are taken into account by replacing μ_L by apparent viscosity μ_a :

$$\mu_L = \mu_a = K \left(\frac{du}{dy} \right)^{n-1} \quad (\text{from Eq. (1)}), \quad (15)$$

In addition, the share rate was approximated to the next value (Farooqi et al., 1980):

$$\frac{du}{dy} \doteq \frac{8u}{D_H} \quad (20)$$

The reason of the best prediction by Schmidt and Friedel's correlation might be that the correlation can account for the liquid properties by Eqs. (12) and (14), while other four correlations do not consider the viscosity effects.

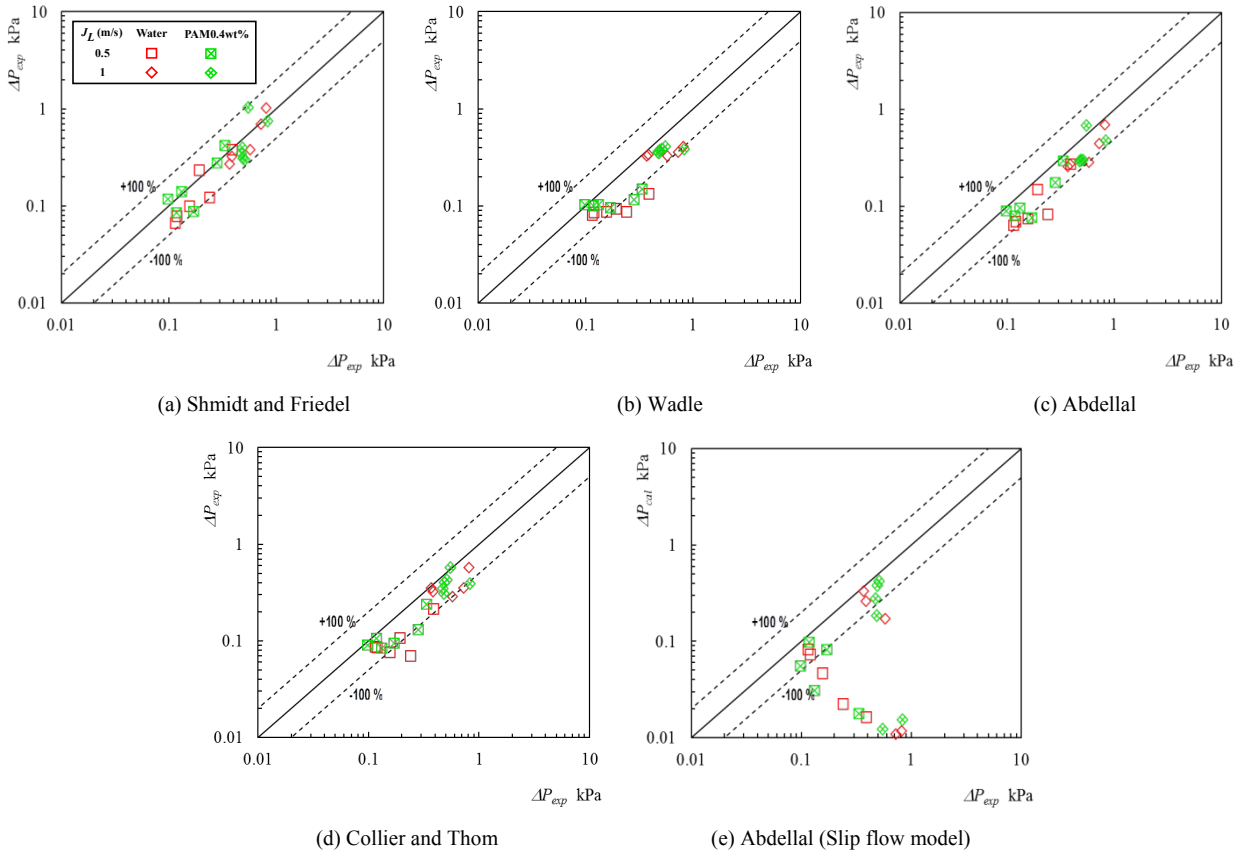

Figure 8. Comparison of present data by correlations

4. Conclusions

Liquid single-phase flow and air non-Newtonian liquid two-phase flow experiments were conducted at room temperature and at near atmospheric pressure using a horizontal rectangular mini-channel with a sudden expansion. The width and the height of the channel were from 3 mm by 3 mm to 6 mm by 3 mm. In order to study the effects of liquid viscosity, water and polyacrylamide (PAM) aqueous solution with mass concentration of 0.4wt% were used as the test liquid. From the present investigation, the conclusions can be summarized as follows:

1. Single-phase friction factor data for water agreed with theoretical values in both laminar and turbulent flow, while the data for the PAM in laminar flow also agreed with the values by using the generalized Reynolds number.
2. Pressure change across the sudden expansion in single-phase flow for both the water flow and the PAM flow increased with the mean velocity in narrow channel. The pressure change for the PAM was larger than water. This results indicated that irreversible pressure drop by the expansion is smaller for the PAM than water.
3. As for two-phase flow pattern, bubble flow, slug flow and annular flow were observed in the wide channel. Bubble size for the bubble flow was smaller for the air-PAM flow than the air-water flow. The liquid film thickness between the gas phase and the channel walls for slug and annular flows was thicker for the air-PAM flow than the air-water flow, due to higher viscosity of the PAM.
4. Pressure change across the sudden expansion in two-phase flow increased with increase in j_G due to the significant effect of the expansion on the reversible pressure rise. The pressure change was larger for the PAM than water when j_G is low. This indicated that the effect of the expansion on the flow disturbance is smaller at low j_G for the PAM flows.
5. Correlation by Shmidt and Friedel, which can account for liquid viscosity, gave the best prediction against the present data on the two-phase pressure change.
